Abstract

The efficacy of water quality policies aiming to reduce or prevent nitrate contamination of waterbodies may be constrained by the inherent delay or ‘time lag’ of water and solute transport through unsaturated (soil) and saturated (groundwater) pathways. These delays must be quantified in order to determine realistic deadlines and thresholds, and to design effective best management practices. The objective of this review is to synthesise the current state of research on time lag, in both the European and North American/Canadian environmental and legislative contexts. The durations of time lags have been found to differ according to differing climatic, pedological, landscape and management scenarios, and elucidation of these driving factors on a watershed scale is therefore essential where water quality is impaired or at risk. Finally, acknowledgement and understanding of time lag is increasingly seen at policy level, and incorporated in the development of environmental legislation. However, it is not yet ubiquitously appreciated, and continued outreach and education in scientific, public and policy venues is still required.

Keywords: Water Framework Directive; lag time; groundwater; unsaturated zone; nitrate
Introduction

The efficacy of water quality policies is influenced by both anthropogenic and non-anthropogenic controls (Bechman et al., 2008). The latter category includes hydrologic (Fenton et al., 2011) and biogeochemical (Jahangir et al., 2013) time lags arising during the migration of excess reactive nitrogen (Nr) through subsurface pathways, which makes any correlation between programme of measure efficacy and water quality improvements difficult (Osenbrück et al., 2006; Meals et al., 2010; Fenton et al., 2011; and others). Time lags have significant consequences for policy design and legislation. Bilotta et al. (2014) recommended that, following the example of the healthcare industry, environmental policies must be informed by thorough and comprehensive review of the scientific research in that field. The purpose of this review paper is to examine the current research on hydrologic time lags, to explore the policy implications arising from their existence, and to compare European and North American scenarios within the context of their unique hydrologic, environmental and legislative backgrounds. Some critical studies are highlighted in Fig. 1, and are discussed within this review.

What is time lag?

The transport of water and nutrients, supplied to surface water bodies and groundwater abstraction points from agricultural, industrial or other sources, may occur via a range of hydrologic pathways, including overland flow, interflow, shallow and deep groundwater flow, and conduit flow (Archbold, 2010), and may also include cycling through a variety of biogeochemical pathways, including uptake into plants and soil organic matter (Sebilo et al. 2013). Transport along these pathways imposes a delay between the implementation of programs of measures (POM) for mitigation, which are designed to improve the quality of ground- or surface-waters (Schirmer et al., 2014), and measurable improvements in water quality. This delay is referred to by a number of different terms, including a ‘memory effect’, ‘delayed response’, ‘residence effect’, ‘legacy effect’ or ‘time lag’ (which is the preferred term in the present manuscript) (Worrall and Burt, 1999; Bechmann et al., 2008; Iital et al., 2008; Wahlin and Grimvall, 2008; Vero et al., 2014; Hamilton 2012; Van Meter & Basu ). Although time lags associated with delays in policy implementation may also occur (Bechmann et al., 2008; Meals et al., 2010), these lags are ignored in the present review. Determining the length of the time lag is of critical importance from a policy and monitoring perspective (Bain et al., 2012), as correlation of the success of a legislative instrument (even assuming 100% implementation) and the current water quality status is not always possible (Fenton et al., 2011), and observations may also be confounded by inter-annual meteorological variability (Bechmann et al., 2008). In addition, prediction of timelines with respect to water quality improvements or deterioration
is challenging (Hering et al., 2010). The subsurface pathway, which includes both the unsaturated and saturated zones, presents particular challenges due to the spatial and temporal heterogeneity of physical properties, the scope for chemical processes and transformations (such as attenuation capacity (Jahangir et al., 2013), difficulties in determining the length of retention times throughout the subsurface (Schueth et al., XXXX), and the influence of meteorological conditions (Hocking and Kelly, 2016). This pathway bears particular importance with respect to nitrate ($\text{NO}_3^-$) and its transformational components e.g. organic nitrogen (Van Meter et al., 2016) and ammonium (Vadas et al., 2007), due to the high mobility of this important agrochemical, and the hazards which it may present to water quality and ecology (Azevedo et al., 2015).

Fenton et al. (2011) and Sousa et al. (2013) have divided the total time lag ($t_T$) via subsurface pathways into unsaturated zone ($t_u$) and groundwater (saturated) ($t_s$) components. The former represents the movement of $\text{NO}_3^-$ from the soil surface (where it may have been applied as fertiliser) vertically through soil and unsaturated bedrock until it reaches shallow groundwater (i.e. the water table). Nitrogen in the unsaturated zone can be either in the dissolved form, as $\text{NO}_3^-$, or as organic nitrogen sorbed to the soil matrix. Van Meter and Basu (2010) refer to the former as the hydrologic legacy, while the latter is referred to as the biogeochemical. Travel of $\text{NO}_3^-$ through the unsaturated zone is dependent upon soil hydraulic properties (such as saturated hydraulic conductivity ($k_s$), porosity ($n$) and pore size distribution), effective rainfall or recharge (ER), and depth of the unsaturated zone. The magnitude of the biogeochemical legacy depends on the clay or mineral content of the soil as well as management factors such as the cropping pattern, levels of fertilizer application, the type of fertilizer applied, etc.

Arrival of $\text{NO}_3^-$ at the water table takes the form of a breakthrough curve, which can be subdivided into the initial breakthrough (IBT), peak concentration (Peak), centre of mass (COM) and solute exit (Exit) (Vero et al., 2014). IBT represents the first arrival of the solute at the water table, and is of particular interest from a policy perspective, as it indicates the trajectory of groundwater quality changes in response to management practices. The middle stages (Peak and COM) are indicative of the bulk of nutrient transport, while Exit represents total flushing of the solute from the profile. As such, although this latter marker may be considered to indicate the fullest extent of $t_u$, it is in reality, difficult to discern from environmental monitoring, as the signal may be extremely low relative to background noise. Attempts to quantify $t_u$ have, to date, been challenging, leading to simplifications, such as an assumption of saturated soil conditions (Fenton et al., 2011). However, a more realistic approach must acknowledge the unsaturated nature of this component; numerical models incorporating the Richards equation (such as Hydrus 1D, VLEACH, or Hydrogeosphere) and site-specific meteorological and soil parameters have been proposed as a viable tool for this approach (Izbicki et
al., 2015; Vero et al., 2017). Other complications include (but are not limited to) denitrification, dispersion and dilution (Nishikawa et al., 2003), equations for which may be incorporated into model supplements (e.g. PHREEQC) (Parkhurst and Appelo, 1999).

Presumably as a result of these complexities, $t_u$ has received less attention in the literature than the $t_s$ portion of the time lag. Simulations of solute transport in baseflow-dominated systems suggest that groundwater NO$_3^-$ concentrations are unlikely to decline for several decades after input has been reduced or stopped, and that increases resulting from historical nutrient loading are inevitable within the short term (Jackson et al., 2007; Jackson et al., 2008; Vertes et al., 2008; Van Meter and Basu 2015). Many studies have also observed $t_u$ in the field (Lindsay et al., 2003; Osenbrück et al., 2006). One such example is provided by Vadas et al. (2007), who found that although soil NO$_3^-$ increased with depth, there were no temporal fluctuations in groundwater NO$_3^-$ over a 2.5-year period subsequent to the implementation of prescribed management practices. These results indicate that $t_u$ was still ongoing, and that the effects of changed management practices in 1997 were yet to be observed at groundwater level, although decreases in NO$_3^-$ could be observed in the upper layers of the soil. Other studies (Bekeris, 2007; Rudolph et al., 2015) have reported observing similar peaks in NO$_3^-$ between 2 and 3 m below ground level in multi-layered soil profiles.

The groundwater travel time ($t_s$) begins once the contaminant ‘breaks through’ the water table and becomes available for lateral transport through the saturated zone. As such, the speed of transport (per unit area) is likely to be more rapid than in the unsaturated zone due to the greater availability of channels through which the solute may be transmitted. However, the total distance to the receptor may vary from very short (leading to a brief $t_u$, where the source is adjacent to a receptor), to decadal (where the groundwater pathway is long). Groundwater, in contrast to water in transit through the soil, is considered as both a vector for nutrient transport to a receptor (such as surface waterbody) and a receptor itself, from which drinking water may be abstracted (Frind et al., 2006). Accordingly, qualitative thresholds are established for groundwater that are distinct from those specified for surface waters. Furthermore, any specific point within an aquifer is liable to receive or transmit water and solutes in three dimensions. The measured concentration of a contaminant at an abstraction point consequently reflects the mean value for the area from which the well is recharged. A greater density of sampling wells in a given area will therefore provide a better indication of actual groundwater quality. Extensive research related to groundwater travel pathways has been conducted in the Chesapeake Bay, United States (Hennessey, 1994; Lindsey et al., 2003; Sanford and Pope, 2013; Van Meter and Basu, In Review, and others). Concentrations of groundwater NO$_3^-$ bay be relatively high (Vadas et al., 2007), which has implications for receptor quality, although denitrification in
groundwater “hotspots” (Jahangir et al., 2013) means that abstracted groundwater samples may not reflect concentrations delivered through the soil to the water table, either spatially or temporally.

**European Context**

Subsequent to the second World War, increased food production became a major European policy objective, and corresponding increases in fertiliser application and land use intensity were observed. However, beginning in the early 1970s, the attention of policymakers shifted towards environmental concerns, with the implementation of the first Environmental Action Program in 1973 (EC, 1974). The primary legislation currently governing water quality in the European Union (EU) is the Water Framework Directive (WFD) (EU WFD; 2000/60/EC, OJEC, 2000). Under this legislation, member states are obliged to attain ‘good’ qualitative status of all ground and surface waters, relative to fixed chemical thresholds (for example, a maximum allowable concentration of 11.3 mg L\(^{-1}\) in drinking water and of 37.5 mg L\(^{-1}\) in groundwater is specified for NO\(_3\)). The WFD specified an initial deadline (2015) by which this objective was desired. However, observed evidence of time lag as well as general scientific consensus indicated that attainment of this objective across all waterbodies was unachievable within the specified timeframe (Craig and Daly, 2010; Fenton et al., 2011; Schulte et al., 2006). Extended deadlines (2021 and 2027) have been implemented in such instances; however, without considering time lags, it is not possible to anticipate the likely efficacy of POM with respect to these later reporting periods (Chyzheuskaya, 2015). National policies have been implemented in response to the WFD, with a view to meeting water quality objectives; these policies specify management practices to control or offset nutrient delivery to receptors. As an example: within the Republic of Ireland, the Nitrates Directive (European Council, 1991) is the main policy mechanism in place intended to avert point and diffuse nutrient losses from agricultural land to water and minimise the risk of eutrophication. The suite of POM specified by this policy includes implementation of buffer strips around surface waters, prescribed livestock stocking rates, closed periods for fertiliser application corresponding to seasonally high rainfall rates, regulations pertaining to storage capacity for agricultural slurry and manures, and limits to fertiliser application rates. Derogation to this latter stipulation (which allows nitrogen (N) application of up to 230 kg ha\(^{-1}\) in Denmark and 250 kg ha\(^{-1}\) in all other countries), however, have become critical to attaining the production goals outlined by the current agri-environmental plans (Food Harvest 2020 (Dept. of Agriculture, Food and the Marine (DAFM), 2010) and Food Wise 2025 (DAFM, 2015)). Notably, all EU member states, apart from France, which does not operate a system which legally defines such rates, have negotiated derogations to the N application limits (van Grinsven et al., 2012). Such negotiations suggest a discrepancy between legislative stipulations and the requirements of the burgeoning European agricultural sector. The percentage of agricultural land subject to these exemptions vary between member states, from only
1.5% of agricultural land in the United Kingdom to 50% in the Netherlands (Grant, 2009). Appraisal of the efficacy of Nitrates Directive POM, at catchment scale, is conducted in Ireland by the Agricultural Catchments Program (ACP) (Wall et al., 2012; Shore et al., 2013; Mellander et al., 2016); similar programs exist in other member states (such as the National Agricultural Environmental Monitoring Program (JOVA) in Norway). As such, the EU faces a particular challenge in designing and implementing environmental policies which are both suitable and effective across its 28 diverse member states (Hering et al., 2010). Bouma et al. (2002) have reported heterogeneity in water quality policy efficacy resulting from soil and land use differences in the Netherlands, and have concluded that ‘fine-tuning’ of regulatory policy and incorporation of geographical information systems are required due to these differences. Such a necessity observed in a relatively small member state (4.15 million ha) is correspondingly greater when similar water quality policies and targets are enacted across the entire EU (432.5 million ha).

Evidence for nitrogen-related time lags in both the unsaturated and saturated zones across Europe is extensive, with peer-reviewed publications originating from many EU member states (Figure 1). Despite this, time lag remains poorly understood by the general public, and specifically, by some of the groups advocating more extensive legislation and POM. In 2010, for example, the European Environmental Bureau purported that time lag was a ‘generic excuse’ to escape more stringent policy measures (Scheure and Naus, 2010). This misconception must be overcome in order to facilitate informed and realistic environmental policies. The following sections will summarise our knowledge of time lags, as observed across the EU.

**Eastern Europe**

Long-term fertilisation experiments have shown that important processes related to N turnover operate on a time scale of decades up to a century, and in several major Eastern European rivers there is a remarkable lack of response to the dramatic decrease in the use of commercial fertilisers that began in the late 1980s (Grimvall et al., 2000). For example, data from 1987 to 1998 in four rivers in this region – the Emajogi and Ohnejogi (Estonia), the Daugava (Latvia), and the Tisza (Hungary) – showed that the nutrient response to management changes was slow and limited in many rivers. Time lags were evident in medium-sized and large catchment areas, suggesting that factors other than reduced fertiliser application influenced the inertia of the water quality response (Stålnacke, 2003; 2004). Further studies in this geographical region, where nutrient inputs have substantially decreased, have found either no downward trends in NO$_3^-$ concentrations (Procházková, 1996; Berankova and Ungerman, 1996), or only limited downward trends (Tumas, 2000) in large river catchments after years of observation.
**Northern Europe**

In Northern Europe, the water quality response to relatively recent decreases in N input to a catchment may be muted by the greater response to post-world war increases in input (Grimvall et al., 2000) and the time lag required for flushing of accumulated nutrients. In 1988, HELCOM in Sweden reached an agreement to reduce pollution transport from land via all pathways (including subsurface and overland), to 50% of the 1984 level by 1995. Success in reducing agricultural leaching, however, has been limited, with only a 15% reduction being achieved during this period (Arheimer and Brandt, 2000). In Baltic countries (Finland and Poland), cessation of state-supported agriculture in the late 1980s and early 1990s, led to reduced fertilizer use. Nevertheless, river N still increased in some areas, which may indicate the ongoing arrival of N that had been migrating through the unsaturated and saturated zones. A review of water quality data from 1981 to 2000 shows that little or no reduction of riverine nutrient loads was achieved from 1995-1999 in response to POM implemented through the Finnish Agri-Environmental Programme in 1995, which intended to reduce N and phosphorus (P) loads by 50% (Granlund et al., 2005). Bechmann et al. (2008) have also observed strong inertia in environmental response in Norwegian catchments to mitigation strategies, including limits regarding stocking and fertiliser application rates. Greater annual N losses have been observed in Norwegian catchments than in other Nordic countries (Vagstad et al., 2001), which may correspond to nationally high application rates and measured soil N surpluses (Bechmann et al., 2008). In such scenarios, it is difficult to disentangle the direct effects of current practices from legacy effects. In Denmark, intensive application of fertilizers and leaching of NO$_3^-$ from the soil and into aquifers began in the late 1950s. These practices resulted in increased groundwater concentrations, which ultimately stabilised at c. 1-2 mm NO$_3^-$ in 1980 (Postma et al., 1991). Andersen et al. (2007) demonstrated that long travel times of groundwater make it difficult to relate current land use and NO$_3^-$ leaching from soils to the discharge of NO$_3^-$ to the marine environment. Interestingly, stringent Danish measures, which go beyond the requirements of the Irish Nitrates Directive (Botta and Kozluk, 2014), have resulted in a decline in NO$_3^-$ leaching from the root zone. Reductions in Denmark’s surface water NO$_3^-$ concentrations (differentiating point from diffuse sources) were identified between 1992 and 2002 (Kronvang et al., 2008), but it took more than 20 years for these reductions to be observed. It therefore remains unclear as to whether such increases in stringency could facilitate achievement of WFD goals within the currently specified timeframes, suggesting that current deadline-based approaches may be less appropriate than a focus on trends and trajectories in water quality.

**Mainland Europe**
In the Netherlands, NO$_3^-$ leaching to groundwater and N discharges to surface waters have been found to be related to N surpluses, hydrological condition, land use, and soil type (Oenema et al., 2005). Indeed, it has been calculated that decreasing the national N surplus by 1 kg ha$^{-1}$ could on average decrease NO$_3^-$ leaching to groundwater by 0.08 kg ha$^{-1}$ and transport to surface waters on average by 0.12 kg ha$^{-1}$ (Oenema et al., 2005). Due to time lags ($t_u$ and $t_s$), however, actual decreases have not matched calculated values (Oenema et al., 2005). Nitrogen surpluses on Dutch dairy farms dropped by an annual rate of c. 7 kg N ha$^{-1}$ year between 1980 and 2005 in response to the implementation of nutrient management legislation, which led to improvements in manure N fertilizer replacement values and reduced fertilizer application (Van den Ham et al., 2007). There has been some improvement in water quality in the Netherlands since this time (Anonymous, 2009); however, van Grinsven et al. (2016) have maintained that current deadlines are unlikely to be achieved and that regionally specific mitigation measures are required. Such results demonstrate the decadal scale of N-related time lags, which is unlikely to be wholly reflected or observed in the current WFD 6-yr reporting periods.

Residence times of injected and environmental tracers in unconfined aquifers across the EU have been found to be as high as 10 years for a variety of catchment sizes and climatic regions (Switzerland, Greece, Germany and France) (Worthington, 2007). These aquifers all exhibit triple porosity but with contrasting flow and storage in their matrices, fractures and channels. The matrices of such aquifers have high storage, leading to increased time lags, whereas briefer time lags occur in the channels and fractures. Wreidt and Rode (2006) have reported that NO$_3^-$ concentrations reaching surface waters in lowland areas of Northern Germany failed to reflect the initial levels of N losses from the surface due to denitrification and long residence times within the groundwater. Intensification of land-use in that member state, subsequent to the 1950s, allowed prolonged loading; the mixing of groundwater of different ages may therefore influence the present delivery of N to surface water. Attempts have been made to model time lags from soil to groundwater (Sousa et al., 2013; Vero et al., 2014) and discharge to surface water (Almasri and Kaluarachchi, 2007) accounting for the three dimensional and process-orientated nature of NO$_3^-$ transport. Such a comprehensive approach was implemented by Wreidt and Rode (2006), in the German context, and indicated a time lag of c. 80-90 years in a 20 km$^2$ catchment. That study also concluded that 80% of the NO$_3^-$ load was removed by denitrification before it reached a surface receptor.

**Western Europe**

Due to a history of glaciation and its position relative to the Atlantic Ocean, Western Europe exhibits a complex unsaturated zone, including highly heterogeneous soil and unsaturated bedrock,
and, frequently, sedimentary aquifers. Consequently, catchments in this region (including Ireland and the United Kingdom) exhibit unique timescales and patterns of NO$_3^-$ transport from sources to receptors. In the UK, the most rapid responses occur in alluvial sands and gravels and limestone aquifers (e.g. Lincolnshire Limestone), while responses in deeper sandstone (e.g. Sherwood sandstone) and chalk aquifers (Hughes et al., 2007) can be on the order of decades. In parts of England, groundwater NO$_3^-$ concentrations are increasing, not due to current practices, but due to the legacy of agricultural intensification over the past 50 years (ADAS, 2007). In addition to agricultural intensification, a number of other factors may be influencing these trends, including climate change and non-agricultural sources (e.g. sewage treatment works and industry). Such sources are less significant in Ireland, which (both currently and historically) emphasises agricultural over industrial production (van Grinsven et al., 2012). The British Geological Survey recently modelled aquifer response times for England and Wales (Jackson et al., 2008). The results of that investigation indicated a timescale of decades (8 and 46 years to reach 50% breakthrough in alluvial and chalk aquifers, respectively) for most aquifer classes, during which time NO$_3^-$ pollution will continue to reach discharge points, despite reductions in contemporary surface loadings (Jackson et al., 2008). In this report, the modelled time for groundwater NO$_3^-$ to decrease in limestone aquifers in the U.K. by 25 and 50% were <10 years and between 18 and 22 years for high and low rainfall regions. Responses for alluvial aquifers in the UK were more rapid, with the time for NO$_3^-$ to reduce by 50% being 8-11 years. These results reflect the generally small, shallow aquifers with short groundwater travel pathways observed in such regions. A study of river water quality in the eastern part of the Humber Basin, NE England, showed that reductions in fertilizer application did not correspond to a proportionate reduction in NO$_3^-$ concentrations in the rivers due to soil processes within the catchment (Neal et al., 2008). Analysis of NO$_3^-$ concentrations from long-term monitoring (1965-2007) of the river Frome in southern England, coupled with modelling exercises, indicated that it would take 12 years to increase mean NO$_3^-$ concentrations by 1 mg l$^{-1}$, compared to 9 years on the nearby river Piddle (Howden and Burt, 2009). This demonstrates that within a relatively small area, subject to the same meteorological drivers, other factors such as soil type, land use and biochemical interactions will influence t$$_1$.

As nutrient management policies are designed to bring fertiliser application rates in line with plant requirements, it is likely that the continued elevation of river N concentrations will be driven, at least in part, by baseflow contributions (t$$_1$) (Spahr et al., 2010). Concomitantly, when increases occur in application rates of fertilizer, water quality may also remain unchanged due to lag time effects. Wang et al. (2016) have presented a long-term (125-yr) modelling approach to NO$_3^-$ transport at regional and national scales in the UK. That approach demonstrated that ‘turning-point’ changes in
groundwater NO$_3^-$ concentrations are to be anticipated in many catchments, on a multi-decadal scale, with IBT alone exceeding 11 months in 21 of the 28 study sites. For 13 of those study sites, the turning-point was predicted subsequent to 2020. In Lough Erne, located in the north-west Ireland, no temporal trend was found over a 25-yr period, despite increased N loading from agriculture diffuse sources (Zhou et al., 2000). Other examples of such a scenario have been observed in the U.K. over a 15-yr period (Tomlinson, 1970) and in a North American site over a 35-yr period (Keeney and DeLuca, 1993). It should therefore be recognised that future water quality hazards may be as yet undetected due to the time lag currently affecting potential contaminants. Fenton et al. (2011) examined time lags through both the unsaturated and saturated zones in Ireland, and concluded that $t_u$ alone could preclude attainment of WFD targets within the first reporting period (2015), thus highlighting the need for environmental trend assessment rather than fixed deadlines, in the design of water quality policies.

The European Indicator Assessment (European Environment Agency (EEA), 2013) indicated poor chemical status of 25% (by area) of EU groundwater; 16% of member states exhibit poor status in >10% of groundwater bodies, while Luxembourg, Belgium, Malta and the Czech Republic are failing in excess of 50% of their groundwaters (EEA, 2013). Within this context, Ireland’s performance as regards groundwater quality should be regarded as highly successful. However, 15% of Irish groundwaters exhibit a trend of increasing concentrations; which is likely to be the legacy of past management practices, in which leached NO$_3^-$ is only now reaching the watertable as a result of prolonged time lag. Analyses of these sites (EPA, 2015) indicated that these trends were significant in two locations, and likely to increase mean N concentration above the threshold by 2021.

**North American Context**

Similar to Europe, North America saw dramatic increases in food production after the second World War, as the farming economy shifted to a new reliance on intensive production practices and a widespread use of pesticides and chemical fertilizers (Novotny 2002). Initially, there was little concern for the environmental implications of these changes. In the 1960s, however, a convergence of factors led to a new environmental awareness in the North American public, including the publication of Rachel Carson’s *Silent Spring* (1962), the growth of the social justice movement (Bouleau 2008), growing problems of eutrophication in Lake Erie (Neerls 2011), and a series of high-profile reports of burning rivers, fish kills and declining shellfish populations (Hines, 2013). This new awareness led to the passing of sweeping new environmental legislation, including the 1970 *Canada Water Act* (1970),

These new policies were unprecedented in their scope and focus on water quality. In the U.S., the dumping of pollutants into common waterways prior to the 1972 CWA was regulated only under “nuisance” law, meaning that it was not treated as problematic unless it was proved to cause unreasonable harm to another’s property right or to the public interest (Hines, 2013). Under the CWA, however, the U.S. established a long-term goal of eliminating all discharge of pollutants to all navigable waterways and, to this end, adopted a variety of effluent limitations for pollutants of concern (Hines, 2013). The Canada Water Act, extended the federal reach of Canadian water law to include issues of water quality, specifically giving it the authority to regulate concentrations of nutrients in cleaning agents and water conditioners (1995). The GLWQA, which came about as the culmination of multiple studies and reports suggesting that nutrient enrichment was the primary cause of eutrophication in the Great Lakes, secured a binational commitment to water quality in the Great Lakes, establishing water quality objectives and providing for the development of water quality monitoring programs (Donahue, 1999).

Despite this recent attention to water quality in North America, little was done initially to address nonpoint source nutrient pollution. Under the U.S. CWA, farmers were not required to meet waste discharge requirements (Dowd, XXXX), and under the Canada Water Act, nutrient pollution was addressed explicitly only as it related to phosphorus in detergents (Hines, 2013). Although the binational GLWQA represented a clear shift from point-source clean-up efforts to an emphasis on nonpoint source pollution (Donahue, 1999), phosphorus (P), not N, was identified as the nutrient of concern, and targets were not set for reductions in N loading. In Canada, both federal, provincial, and local agencies now play a role in managing nonpoint source pollution, in some cases under source water protection plans (Simms et al. 2010). Most strategies within such plans involve voluntary participation by farmers, with local agencies promoting and providing support for implementation of best management practices. In 1987, the U.S. amended Section 319 of the CWA, to cover nonpoint sources, but, as in Canada, the actions under Section 319 include only indirect control measures, with state management programs providing information, grants, and technical assistance (Griffiths and Wheeler, 2005).

At the regional and local scales, significant efforts have been made to reduce nonpoint source \( \text{NO}_3^- \) pollution. For example, in 1987, the Chesapeake Bay Program, a partnership of multiple states and the U.S. EPA, committed to reducing “controllable” loading of N to the Chesapeake Bay by 40% by 2000 (Van Meter & Basu, in review). Although this commitment led to extensive implementation
of nutrient-based best management practices in agricultural areas (Sharpley, 1999, Hennessey, 1994), a 2011 report evaluating the success of these efforts notes that progress has been limited and that the nutrient reduction goals have still not been attained [Reckhow et al., 2011]. Similarly, in 2008, the Mississippi River/Gulf of Mexico Watershed Nutrient Task Force created an action plan calling for a reduction of the Gulf of Mexico’s summer hypoxic zone to less than 5,000 km$^2$ by 2015 (Rabotyagov, 2014; USEPA, 2008). In 2014 and 2015, however, the dead zones were 3-4 times the stated goal (13,085 km$^2$ and 16,768 km$^2$, respectively), despite the millions of dollars spent on watershed BMP. The goal has now been postponed to 2035. Across the U.S., the EPA has reported impairment of more than 33,000 waterbodies due to nonpoint source pollution (USEPA, 2011), and successful remediation of only 354 (or 1%) these waterbodies, despite spending on the order of $200 million annually to improve water quality under CWA Section 319.

In the following two sections, we will focus on current research and recent case studies regarding N-related time lags in Canada and the United States.

Canada

In Southern Ontario’s Grand River Watershed (GRW), N surplus values have decreased on the order of 10-40% since reaching a peak in the mid- to late 1970s, due to a combination of improved nutrient management, increasing crop yields, and decreases in atmospheric N deposition (Van Meter & Basu, submitted). Decreases in N concentrations and loads, however, have been slow to follow, and elevated NO$_3^-$ levels in both surface and groundwater are increasingly a threat to drinking water quality, particularly in rural areas (Goss et al. 1998; Sousa et al., 2013; Corkal & Adkins, 2008; Wassenaar, 1995). A cross correlation analysis between N inputs and stream N concentrations revealed lag times across the GRW to range between 15-30 years, with the longest lags being associated with summer concentrations (REF). In a study carried out in upland areas of the GRW, Pearce and Yates (2015) found no association between the abundance and location of agricultural BMPs and improvements in water quality during the summer season over a period of 3-15 years after their implementation.

A detailed study of NO$_3^-$ lag times was conducted in Ontario for the Thornton well field, a site providing approximately 6000 m$^3$/day of water to the town of Woodstock (Sousa et al., 2013; County of Oxford, 2011). Application of N fertilizer in agricultural areas around the well field had led, in the 1990s, to NO$_3^-$ concentrations above the maximum allowable concentration (MAC) of 10 mg-N/L. In response, the County of Oxford purchased approximately 100 ha of land in the capture zone of the well field in 2002 and then rented this land back to local farmers, with a strict cap being placed on fertilizer application rates. Concurrently, detailed site characterization was conducted to evaluate
BMP performance by monitoring NO$_3^-$ t$_u$. Average soil pore water NO$_3^-$ concentrations dropped from approximately 20 mg/L to 10 mg/L NO3-N within 2 years of a 50% reduction in fertilizer application, while NO$_3^-$ in groundwater wells reduced approximately linearly from ~10 mg/L in 2002 to 7 mg/L in 2013 (Rudolph et al. XX). The slower reduction in the wells compared to the pore water concentrations is reflective of t$_u$. Numerical modelling conducted at the site (Sousa et al, 2013) indicated total time lags ranging from 7-40 years, with anywhere from 26-82% of that time being within the unsaturated zone (Sousa et al. 2013).

Lag times associated with NO$_3^-$ contamination of drinking water wells have also been a significant problem in western Canada, for example, in the permeable sands and gravel of southwestern British Columbia’s Abbotsford aquifer, an unconfined transboundary aquifer that has supported intensive agricultural activities for decades (Wassenaar, 1995; Mitchell, 2001; Cox and Kahle, 1999; Zebarth et al., 2015). Elevated NO$_3^-$ concentrations as high as 12.0 mg NO$_3^-$N/L were first reported for the aquifer in the 1950s, and in 1989 63% of sampled wells were found to have concentrations exceeding the Canadian MAC of 10 mg NO$_3^-$N/L (Liebscher et al., 1992). In 1992, the government of British Columbia signed into law the Code of Agricultural Practice for Waste Management (B.C. Ministry of Water, Land and Air Protection, 1992; Wassenaar et al., 2006), which required implementation of a variety of new BMPs, including improvements in livestock waste management and optimization of fertilizer application rates. The development of alternate markets for manure has led to the export of manure from the area and resulted in an estimated 50% reduction in the agricultural N surplus between 1991 and 2001 (Schreir et al., 2003). Despite such interventions, intensive monitoring has shown little improvement in mean groundwater NO$_3^-$ concentrations (Zebarth et al., 2015). A comparison of NO$_3^-$ concentrations between 1993 and 2004 in 31 monitoring wells showed increases in 64% of all wells, with a mean increase of approximately 6 mg NO3-N/L. When both domestic and monitoring wells are considered, 59% exceeded NO$_3^-$ drinking water standards (Wassenaar, 2006).

United States

One of the largest U.S. programs to improve water quality has been the U.S. Conservation Reserve Program (CRP), which subsidises farmers for the voluntary removal of environmentally sensitive land from agricultural production (USDA, 2016). The CRP was enacted in 1985, and, as of 2006, operates at an annual cost of approximately $1.7 billion (Ribaudo, 1989; Hansen, 2007). Assessments of program benefits, however, have been mixed. Water quality improvements have been valued at approximately $389 million per year (Hansen, 2007), but how these modelled
economic benefits translate into actual reductions in NO$_3^-$ loads, particularly at the watershed scale, remain largely unclear.

Although there has been widespread implementation of agricultural BMPs in recent decades, most studies within the US have found only minimal improvements in water quality, and lag times have been found to be a primary cause of such short-term lack of success (Meals et al., 2010). Field studies indicate that NO$_3^-$ lag times in small and large watersheds across US can range from 4 years to more than 50 years (Meals et al., 2010). Tomer and Burkart (2003) report lag times > 30 years in two 30 ha Iowa watersheds, such that groundwater NO$_3^-$ concentrations in 2003 was being influenced by fertilization in the 1970s. Owens et al (2008) reported that the response in groundwater quality to changes in fertilization rates can range from 4-10 years, even in very small (<2ha) watersheds, and that briefer lag times (c. 3 yrs) occur when clay confining layers forced groundwater discharge pathways to be shallow. In another field study in the Pequea and Mill Creek Clean Water Act Section 319 National Nonpoint Source Monitoring Program (NNPSMP) Project (1994–2003) Pennsylvania, changes in fertilizer applications did not result in stream NO$_3^-$ reductions, which was corroborated by groundwater age dating that indicated travel times of 15-39 years (Galeone, 2005).

In the Walnut Creek Restoration NNSMP project in Iowa, 1224 ha of row-crop land was converted to native prairie over a period of 14 years (1991-2005) in the 5218 ha Walnut Creek watershed. Studies of stream and groundwater quality (Schilling and Spooner 2006; Tomer et al. 2010) showed statistically significant decreases in NO$_3^-$ concentrations in both waterbodies, although the decreases lagged the establishment of reconstructed prairie by 3 years. Notably, this lag was clearly observed at a catchment scale, but became obscured across the entire river basin as a result of heterogeneous land uses. Using a coupled groundwater modelling (MODFLOW) and geographical information system approach (GIS), groundwater travel times were estimated to range between 2 – 308 yrs, with mean travel times between 10-14 years (Schilling and Wolter, 2007; Basu et al 2012). It was also determined that increased density of tile drainage would decrease $t_r$, and hence $t_f$, due to faster routing of flows through the subsurface pathways (Schilling et al 2012). Van Meter and Basu (2015) developed a reactive transport model for the same site, and found the trajectories for NO$_3^-$ recovery at the catchment outlet could best be described by considering both the hydrologic N legacy (N in a dissolved form, present in both soil and groundwater) and a biogeochemical N legacy (N that has undergone biogeochemical transformation to organic N and is retained within the soil matrix). Those results suggest that while it may take 5 yrs to achieve a 50% concentration reduction at the water table beneath converted sites, the time frame for achieving a similar reduction at the catchment outlet (reflecting $t_f$) would be strongly dependent on the spatial distribution of converted sites within the watershed and could range from 8 yrs to multiple decades.
In the Chesapeake Bay (CB) watershed, efforts to reduce NO$_3^-$ loading have been ongoing for the last two decades, but have yielded limited success. Groundwater travel times have been documented to range from years to decades, and a modelling study in the Delmarva peninsula to the East of CB revealed $t_\tau$ of the order of several decades before concentration reductions will be achieved (Sanford and Pope, 2013). Van Meter et al (2016) used the ELeMENT travel time distribution model coupled with 200 yrs of N input data to estimate that 55% and 18% of the current annual N loads in the Mississippi River and the Susquehanna River Basins (the latter of which drains into CB) were older than 10 years. In another study, Kauffman et al. (2008) developed a three-dimensional groundwater flow model to examine the effects of land use and groundwater travel times on the distribution of NO$_3^-$ in surface- and groundwater across an approximately 1000 km$^2$ area of the southern New Jersey Coastal Plain in the eastern U.S. Model results showed a continual elevation of NO$_3^-$ over background levels for multiple years even in scenarios where there was an immediate ban in fertilizer application. In another multi-site modelling study, McMahon et al. (2008) used groundwater tracer data (tritium, helium, and sulphur hexafluoride) along with a MODFLOW model to assess potential changes in water quality in public supply wells in California Nebraska, Connecticut, and Florida. Time lag between contaminant inputs and the arrival of peak concentrations at the supply wells ranged between 6 and 30 years, with briefer $t_\tau$ in wells with larger fractions of young water. The times required to flush 99% of the total NO$_3^-$ mass after a complete cessation of inputs ranged from a mean of 17.5 yrs in the fastest contributing areas to more than 200 years in the slowest contributing areas.

Implications

Efficacy of Intervention Strategies

As evidenced by examples from the international literature, time lag cannot be dismissed as a ‘generic excuse’ (Scheure and Naus, 2010) considering the diverse soil, groundwater and landscape scenarios which influence its duration. Hence, where a waterbody fails to achieve water quality targets within a designated timeframe, it is critical to ascertain the influence of time lag in that catchment, in order to determine whether there has been an implementation or an efficacy issue. In other words, assuming full and timely implementation, it is impossible to observe the effects of intervention measures before the minimum lag time has elapsed, and before sufficient amounts of legacy N accumulated within the soil and groundwater have been flushed (Fenton et al., 2011). Where desired improvements in water quality are not met, it may be tempting to impose changes to the utilized intervention measures, particularly in response to political or cultural pressure. Indeed, a lack of understanding of hydrological principles may understandably lead the public to believe that current
measures are not strenuous enough. Such a scenario may be particularly likely when qualitative thresholds and fixed deadlines are the primary evaluation tool (as in the EU), rather than trend analysis (as in parts of the United States e.g. North Dakota (Vecchia, 2003)). By characterising catchments exhibiting poor or declining water quality with respect to their associated time lags, we may be better able to evaluate the appropriateness of a given suite of intervention measures, and to determine whether either changes or extended deadlines are required. As demonstrated by Wang et al. (2016) and Vero et al. (2017), a modelling approach coupled with appropriate soil, geological and meteorological data, may provide an optimal means to address this need.

Policy

In their commentary on agenda and policy dynamics, Baumgartner and Jonas (1991) noted that government policy typically exhibits prolonged durations of stability interspersed with briefer periods of extreme instability and change. Such changes may be reactive and strongly influenced by changes in prevailing influences on public opinion. Baumgartner and Jonas (1991) further noted that changes in public understanding of a scenario may be influenced not only by scientific research, but also by emotive or dramatic events. Water quality is obviously a politically sensitive issue, with almost insurmountable importance to sustainable growth and support of the growing global population. It is therefore important that the design of stable and effective environmental policies not be disproportionately influenced by any one group or opinion (Browne, 1990), but rather, should incorporate both public participation and scientifically reliable information.

Taking an example from the Republic of Ireland; in a 2006 debate on water quality in the upper house of government, a Senator claimed to obtain his scientific information on the issue of nitrates as follows; ‘One does not have to be a scientist to appreciate the reality of the situation…I rely on information in the newspapers for this debate, some of which is very well-informed’ (Seanad Éireann, 2006). This reliance on popular publications was rather than any of the national EPA water quality reports (EPA, 2005a; EPA, 2005b), or one of the many peer-reviewed articles on water quality published, both nationally and internationally, that year. While popular publications no doubt have a place in environmental discourse, they cannot be assumed to be free of bias and opinion, nor to provide a comprehensive synthesis of the scientific literature. Hence, the former source should not supersede the latter. The consequences of time lag in relation to NO$_3$ contamination were similarly dismissed by the European Environmental Bureau (Scheure and Naus, 2010). However, it is encouraging to note that such a stance is not ubiquitous in the realm of policy arena groups; the European Environmental Assessment acknowledged that ‘It is very difficult to prove a direct context between the application of nitrogen fertiliser in agriculture and the NO$_3$ content in groundwaters as
there is often a significant time lag between changes in agricultural practices and changes in NO$_3^-$ concentrations in groundwater of up to 40 years, depending on the hydrogeological conditions’ (Lindinger and Scheidleder, 2004). Likewise, the United Kingdom Department of Environment, Food and Rural Affairs (DEFRA) recognised in their 2008 report that prolonged $t_r$ within catchments may obscure improvements in water quality, and the Parliamentary Office of Science and Technology (POST) (2004) stated that ‘the complexity and geographical variability of catchments across the country [UK] means that no single set of DPW [diffuse pollution of water] reduction measures will be universally applicable.’

It is well established within scientific literature that time lags may present a significant impediment to achieving NO$_3^-$ reduction goals within the designated reporting periods (Cherry et al., 2008). Nevertheless, there remains a discrepancy between the current legislative timeframes of the WFD (6-yr periods) and the decadal to multi-decadal timescales associated with the physical movement of NO$_3^-$ through the subsurface. The multiple difficulties posed by a threshold-based approach to environmental assessment have also been noted in relation to air emissions from EU member states (Sustainable Europe Research Institute, 2011). Accordingly, a trend-based approach may provide a more effective measure of interventions designed to decrease NO$_3^-$ levels in receiving water bodies. Burt et al., (2010) highlighted the need for long-term water quality monitoring in order to quantify these lags, as monitoring programs <10 yrs in duration were found to not only fail to capture the full extent of prolonged $t_r$, but also, are strongly influenced by inter-annual meteorologic variability. This is a sentiment echoed throughout the literature and the efficacy of such extensive datasets with respect to $t_r$ and trend analysis has been demonstrated both in the European (Burt et al., 2008) and North American (Stets et al., 2015) contexts. A commitment to long-term monitoring should therefore foster improved assessment of $t_r$, and hence, facilitate the design of implementable, effective, realistic and timely water quality policies.

Conclusions

The present review has demonstrated the ubiquity of N-related time lags in both the saturated and unsaturated zones as a hydrological occurrence, and the consequences of these lags across national and international scales. There seems ample evidence to suggest that a consideration of time lags must now become standard in the design of water quality policies, and that specific targets and deadlines prescribed by current policies may need review in light of current research.
